DEVELOPMENT OF A NEW TECHNIQUE FOR IMAGE RECONSTRUCTION, ENHANCEMENT, AND VISUALIZATION

Principal Investigator: Dr. Steven A. Orszag

1. INTRODUCTION

The problem of describing and reconstructing a surface, both analytically and visually, has been extensively addressed in this work. Various algorithms have been developed, tested, and compared and several conclusions have been reached. They are: (1) If the surface information is given on a uniform grid, the surface is best described by a set of contour plotting routines that exploit the GL graphics libraries both in a solid as well as a wire-mesh framework; (2) If the surface information is given on a non-uniform grid, the surface can be described by Delaunay triangulation, a sophisticated graphics computer, or by interpolation back to a uniform grid. Each of these methods possesses certain advantages over the others. In the event of insufficient information on the surface, two basic methods have been employed: (1) an algorithm to fill in "missing" information that employs Delaunay triangulation; and (2) interpolation amongst various grid points of known data assuming that the surface is relatively smooth. In the case of distinct missing information on outliers (regions of the surface possessing extremal properties missing from the original surface), no progress has been made.

2. TECHNICAL BACKGROUND

In general, a surface is described by a function, such as f(x,y,z)=const Alternatively, a surface can be described by z = g(x,y), with the understanding that g(x,y) can take on multiple values of the surface folds back on itself. A typical area of interest to the Air Force is a surface reconstruction of photographs taken from high altitude. In some portions of the photographs where high resolution is needed, certain blurriness associated with absence of resolution may need to be improved. Furthermore,

of Grand or Special

. 2 -

the need to remove some white noise from the picture may result in a distinct sharpening of the picture. Statistically, as long as the surfaces involved are very smooth, standard regression analysis could very successfully yield the desired results. However, the information that one wants to obtain are more often than not associated with some characteristics that are absent from the general smooth background of the images.

There are two distinct problems in surface reconstruction:

- (i) Decomposition of the surface into elements.
- (ii) Smoothly connecting these elements by interpolation.

The best solution to these problems is different for uniform grids than it is for non-uniform grids.

For non-uniform grids, the first problem can be solved by the Voronoi-Delaunay construction. Each vertex is surrounded by a Voronoi cell, defined as that cell that contains points which are closer to this vertex than to any other. The boundaries between neighboring Voronoi cells are lines, equidistant from a pair of vertices. Connecting all such pairs by links generates a Delaunay triangulation. We exploit this geometrical construction by observing that each triangle (abc) involves vertices which are Voronoi neighbors. There is a point Y where all three Voronoi cells (a,b,c) touch. By construction, all three vertices a,b,c are equidistant from Y so that these points are on the circle centered on Y. No other vertex can exist inside this circle by definition of the Voronoi cells. This property has been used in the construction of an incremental algorithm for Delaunay triangulation. We have developed an algorithm that accomplishes this triangulation recursively. Strictly speaking, the task is to add a point to an existing triangulation of N points. An added point exists and is contained inside one of the existing triangles. If we connect the new point to the vertices of the triangle in which it lies, we get the zeroth approximation of the triangulation of N+1 points. This triangulation is good away from the new point, but must be rebuilt in the local neighborhood of the new point. The maximum area of reconstruction is given by the circle centered on Y, and in general, it requires only a finite number of bond flips (triangle reconstructions). A recursive flipping algorithm can be derived and is very fast. The most costly operation in this incremental Delaunay triangulation is the search for the triangle surrounding the new point. Straightforward scanning takes O(N) time, but preprocessing the data accelerates the search by the following strategy.

One can order the vertices along any specific curve so that neighbors on the curve will be always close to each other on the plane. (This is a version of the traveling salesmen problem.) Such an ordering of initial points takes $O(N \log N)$ time. This ordering is needed to be performed only once, after which various progressive surfaces can be drawn using the same coordinate system. Degenerate cases, when the points are too close to each other or the (N+1)st point is too close to the side of the Nth triangulation, are treated separately to prevent numerical instabilities.

The second approach is based on the graphics implemented in the graphics terminals of Evans and Sutherland. The points are loaded on the system and are displayed simultaneously with x,y, z coordinates all belonging to the same surface. The surface can be rotated around each of the three axes and cutting planes have been introduced to isolate specific projections of the surface on a plane of choice. On a plane of choice, curves have been interpolated using optimal bicubic splines. The points are added on the splines and the files of the individualized planes get re-assembled. A perpendicular plane to the original set of parallel planes is being introduced and the added points in each of the previous planes is compared to the initial set of points on this cut plane. A least-squares estimator is performed to decide on admissibility or inadmissibility of the added points. If the set of points added to the global grid is admissible, a point-by-point elimination process for the added points is invoked until the set of added points becomes admissible. The set of points that are then admissible per

perpendicular plane are then added to the global grid and the process may be repeated until no more points are admissible. At that stage, the entire file is re-loaded on the graphics system and a surface reappears. The surface can be described by the actual collection of dots, wire-mesh, or by standard graphics shading routines on the graphics processors. We are now in the process of adapting these algorithms to the SGI GL libraries.

The third case for the non-uniform grid can be handled in two different ways. First, a uniform grid is imposed in the x-y plane. At each grid point, a characteristic radius is introduced. Each point in the x-y plane, x_i, y_i is taken into account. The number of points p in the enclosed domain is recorded and a pth Lagrange interpolation scheme is introduced to compute the value z associate with the said grid point. When all the uniform grid point values have been obtained, the interpolation scheme is checked against each existing original point. In other words, each original point is attempted to be recomputed to check for accuracy. This is done with variable orders in order for outliers estimates to be rejected. In the second case, at any vertex in the Delaunay triangulation, an arbitrary number of triangles can meet and the property of smoothness at the vertex requires a large number of local parameters. We have the following construction that satisfies all the required smoothness conditions. The Gauss formula for planes of the corresponding triangles meeting at a vertex has been used. The smooth function so obtained passes through all its neighbors. This function is usually a sum of about six terms. Three of such functions are connected inside each triangle by a similar Gauss interpolation resulting in an explicit local set of rational functions within each triangle matching their neighbors with any prescribed smoothness. The addition of the interpolated points to the original triangulated surface is composed by the set of points at the center of the Delaunay circles, i.e. vertices of the Voronoi graph which are always located in the voids of the Delaunay triangulation. Adding these circle centers does not require a search and is numerically stable. It roughly doubles the number of points omitting the points whose Delaunay circle radius is smaller than a given criterion to avoid condensation of points. After a few steps, the plane is completely covered and the process is complete.

The issue of describing a surface on a uniform grid is different in nature. An aerial photography or topographic description of a surface can in principle be described on a uniform grid since the data gathering can be digitized according to the data gatherer. At this juncture, a missing observation on the uniform grid is interpolated using standard Lagrange interpolations and data contained within noise can be filtered out by invoking standard FFT techniques. In particular, a combination of low and high-pass filters can isolate specific structures by sharpening the domain of resolution. It is believed that this technique may have the potential of image enhancement.

One of the major goals in this study is the ability to characterize an irregular surface, in particular, non-uniform surfaces obtained either from exterior sets of observations or from solutions of partial differential equations of moving fronts or equipotential surfaces. For example, the system of detecting irregular conductivity of an internal human tissue is dependent on surface potential and conductivity. A solution of the potential problem inside the bulk with isolation of equipotential surfaces is hoped to improve visualization of internal irregular tissues. It is for such surfaces that the non-uniform grid methodologies developed here will be useful.

3. IMPLEMENTATION

We have developed the algorithms specified in Tasks 1-3 of the original proposal. These are exemplified by the attached source code in Appendix I. For Task 4, we have developed a menu-driven user-based interface that is displayed with all its functions in

the attached plots. The use of this interface and code is elementary and requires minimal learning time. The code interface is implemented by use of a mouse within the graphics window. For Task 5, we provide various sets of examples of non-uniform as well as uniform grid systems. The uniform grid graphics visualization displays a system borrowed from microelectronics of contact hole printing when the surface of the electromagnetic energy intensity is displayed above a given surface. Multi-resolution is used in these calculations to address the requirements of circuit designers. Furthermore, we attach two different circuit designs (see Figs. 1-2) obtained for uniform grid implementation of two separate logic patterns for wiring and memory triggers. In both cases, GEOFORM gave a reasonably satisfactory description of the circuit and its associated resolution.

For the non-uniform grid systems, we have tested this method on geologic data, Martian topography, vortex sheets in hydrodynamics and also on a sculpture reconstructed from a few hundred points. Sometimes smoothing was needed, i.e., the points were iteratively moved towards the local second-order surfaces, least-square fitted to the nearest neighbors. Since this fit was local, it did not erase the small details at the surface of larger structures. Everything was smoothed at its own scale. This algorithm is surprisingly efficient. The Mars topography reconstruction required only 2% of randomly chosen data points. The sculpture was reconstructed from just 600 points, and the roll-up of a vortex sheet was simulated using only 1000 points. In Figure 3, we display the Delaunay triangulation of the initial mask. The reconstructed surface is displayed next to this triangulation and the internal variations in the density of the triangulation manifests in different shading to create the necessary visualization of the actual original mask. The other two segments of Figure 3 involve the reconstruction of very sharp mountain peaks on the Asian continent where the triangulation density indicated initially a sharp gradient that led to the reconstruction of the Himalayan peaks.

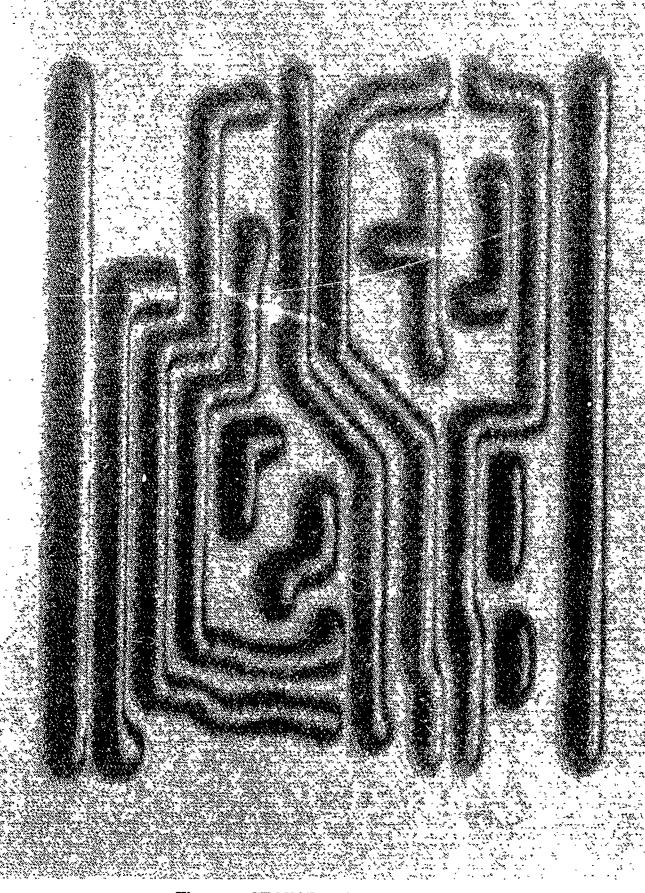

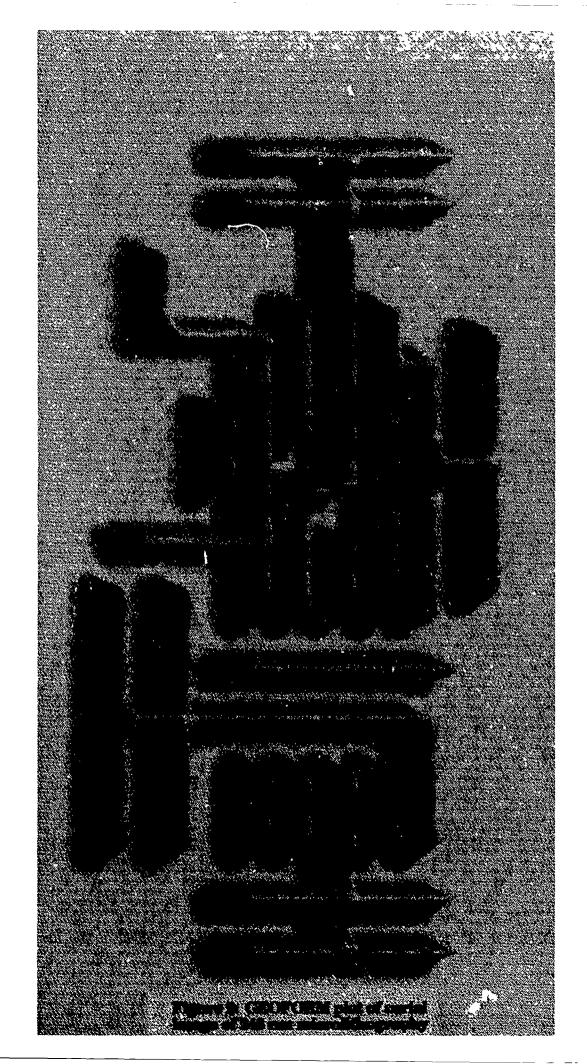

Figure 1: GEOFORM plot of aerial image of 365 nm microlithography

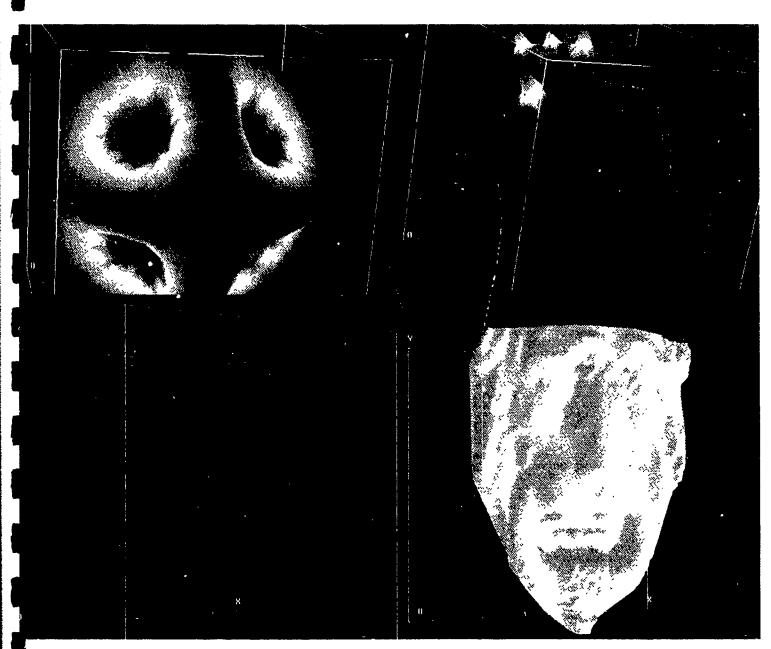

Figure 3: Examples of GEOFORM applications

Higher intensities (higher heights of the mountain peaks) are illustrated in red to emphasize the reconstructed of the missing peak. This technique could be very useful to reconstruct surfaces obtained from high altitude with blurred resolution at the extremes. The fourth quadrant of Figure 3 illustrates a reconstructed sphere with cavities inside. It could be particularly important to use this technique in the simulations of porous media where specific flow channels can be obtained to determine porosity of new materials. The dynamics of pore sizes is under current investigation.

In Figures 4-5, we display graphically the detailed mechanism of edge detection in the GEOFORM code. It is menu controlled and specific points associated with the edge of a given surface are determined locally or globally. In particular, a zoom window provides the ability to zoom in on an edge of interest. The particular example given is that of refining the edge of a 'rabbit' shaped region. It is apparent that even rough resolution suffices to solve the problem. A second graphical option associated with a collection of points is the imposition of the interior Delaunay triangulation embedded in these points.

To explain how we do this, let us consider a collection of points which lie along lines. The points may be given in any order. Our objective is to divide the set of points into subsets, such that all the points in one subset lie along a line. In other words we want to reduce our initial set of points to a set of clusters of close points. We then compress these clusters to "skeletons". These skeletons are represented as graphs with logical links between points. After this compression, one can either compare graphs with a lookup table of standard elements or simply transmit the graph. At each link of the graph one can store the number and mean dispersion of the compressed nearest points, so that one can return to the thick lines after transmission by randomly distributing points alongthe links. As compared to standard methods, this one seems to be especially well suited for graphic objects such as handwriting, fingerprints, space photos or maps.

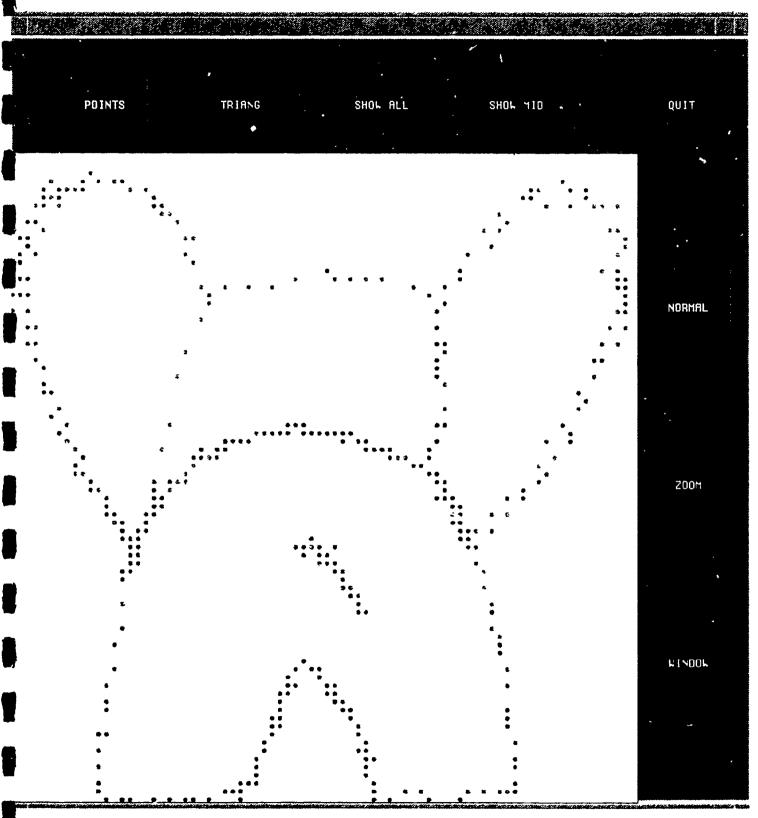

Figure 4: Edge detection: rough boundary of 'rabbit'

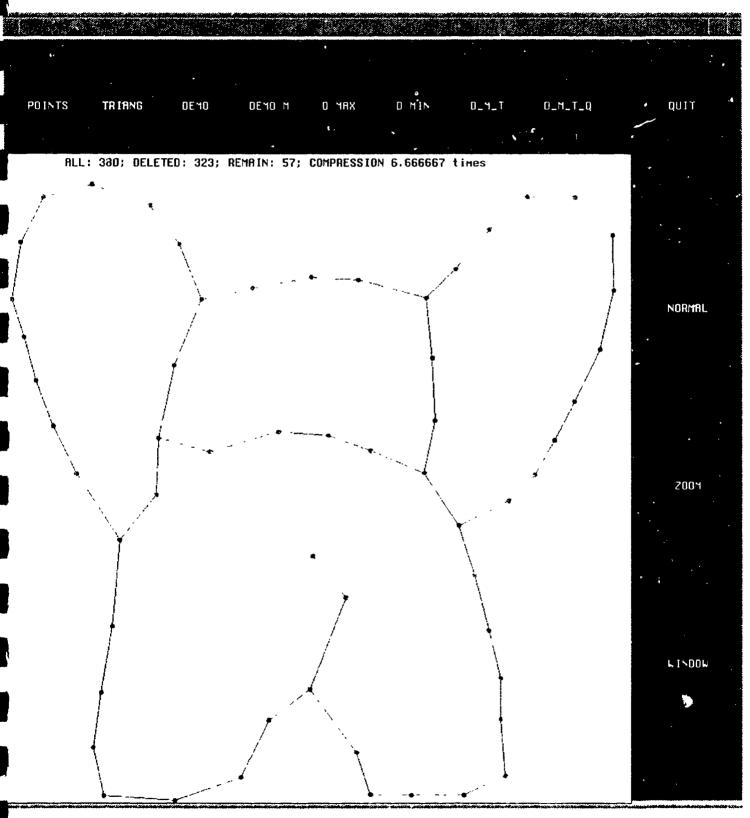

Figure 5: Edge detection: refined boundary of rabbit using GEOFORM

We use the following method. First, we construct the Delaunay triangulation of the set of given points, and then we begin a transformation of the triangulation which will extract the points lying along lines. We have developed a set of functions described below that we apply to our triangulation. The function DELETE MAX EDGE deletes the longest edge of the Delauray triangulation. The function DELETE MAX EDGE IN TRIANGLE deletes the longest edge, which does not "disconnect" the triangulation, i.e. we delete the edge only if each of its end points has at least three neighbors. The function does nothing if such an edge does not exist. The function DELETE MIN EDGE deletes the shortest edgeof the Delaunay triangulation. The function MERGE MIN EDGE merges the end points of the shortest edge into one point. This new point is placed at the center of mass of the two old points taking into account the number of points which were merged into the points before. The function MERGE MIN TRIANGLE merges the three vertices of the smallest triangle (by area) into one point. The new point is placed at the center of mass of the three vertices, taking into account the number of points which were merged into the vertices before. With these functions in hand, it remains to determine the order of applying them to the triangulation. To explore this question, we developed a tool implemented on IRIS workstations which allows us to choose which function to apply to the traingulation at any time to achieve the best line extraction. The tool collects the information about all steps and prints out the statistics on the working process. This helps to determine the best strategy for applying our functions.

The reconstruction of Martian surfaces is displayed in Figures 6-11. These illustrate extremes obtained from higher Delaunay triangulation densities with missing peaks. A solid surface with proper shading is reconstructed to visualize the actual surface obtained from discrete pieces of information.

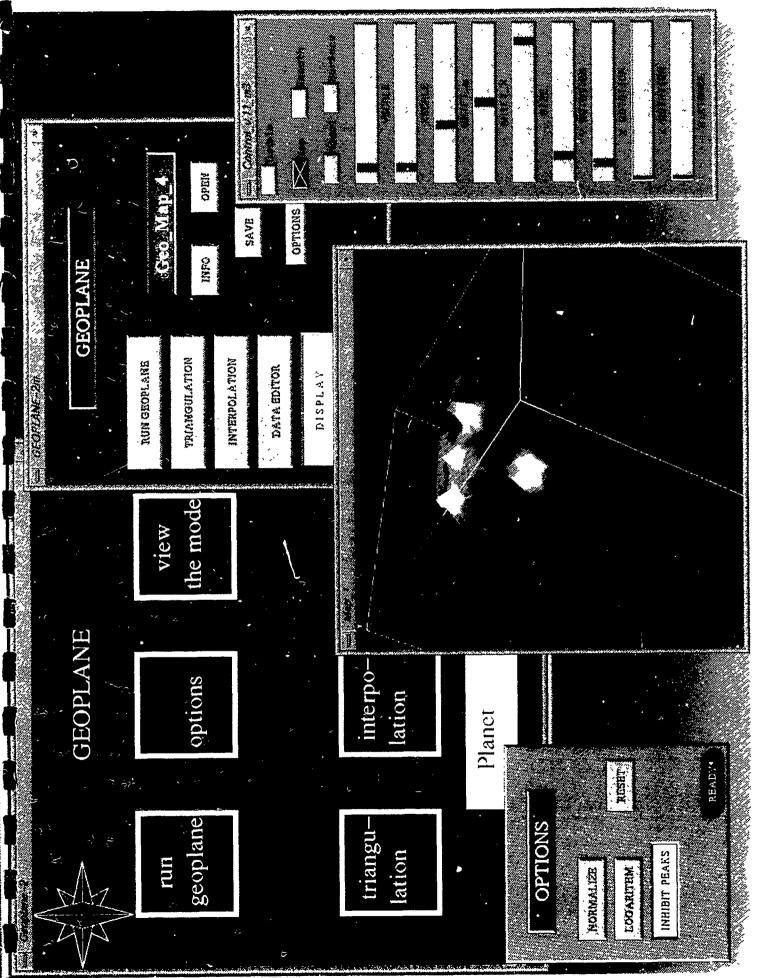

Figure 9: Menu-based mapping environment of GEOFORM

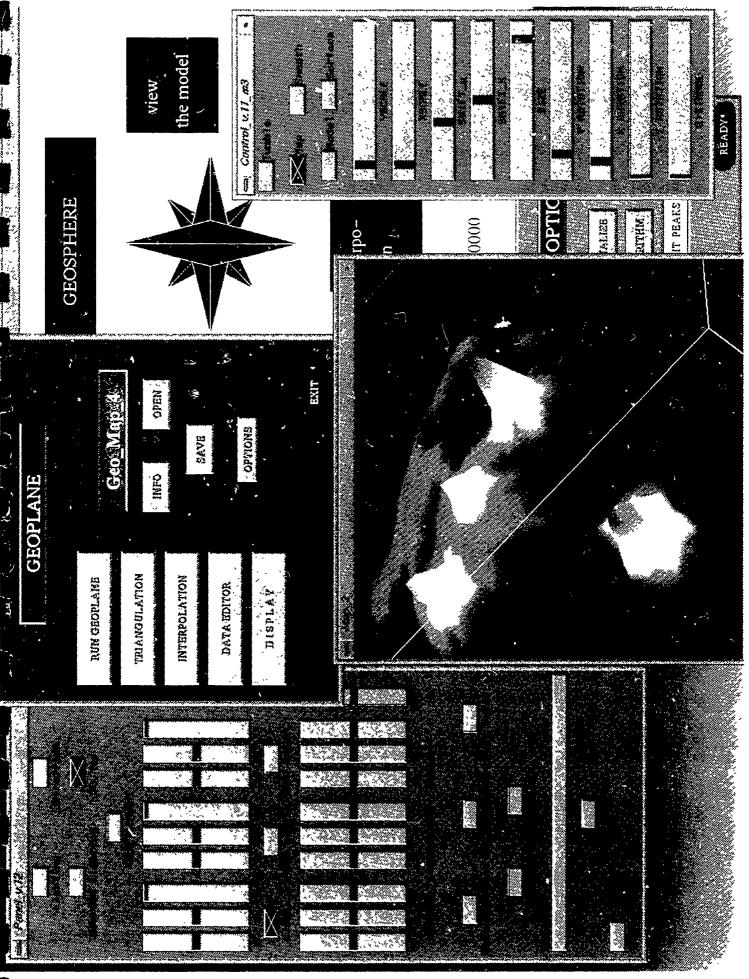

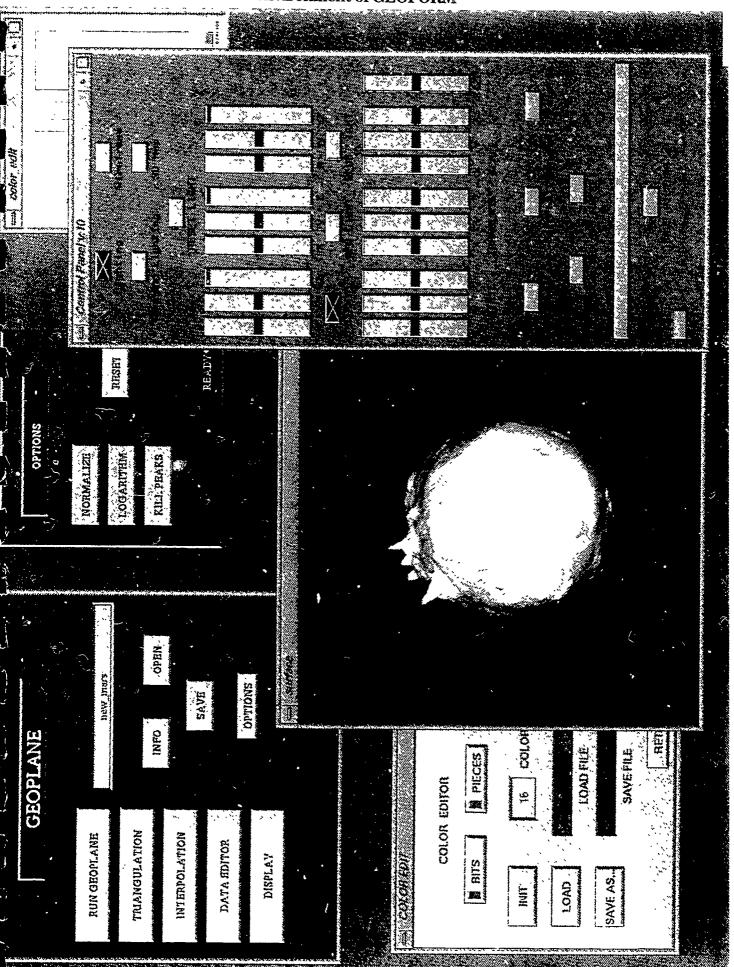

Figure 10: Menu-based zoom-in environment of GEOFORM

Figure 11: Menu-based lighting environment of GEOFORM

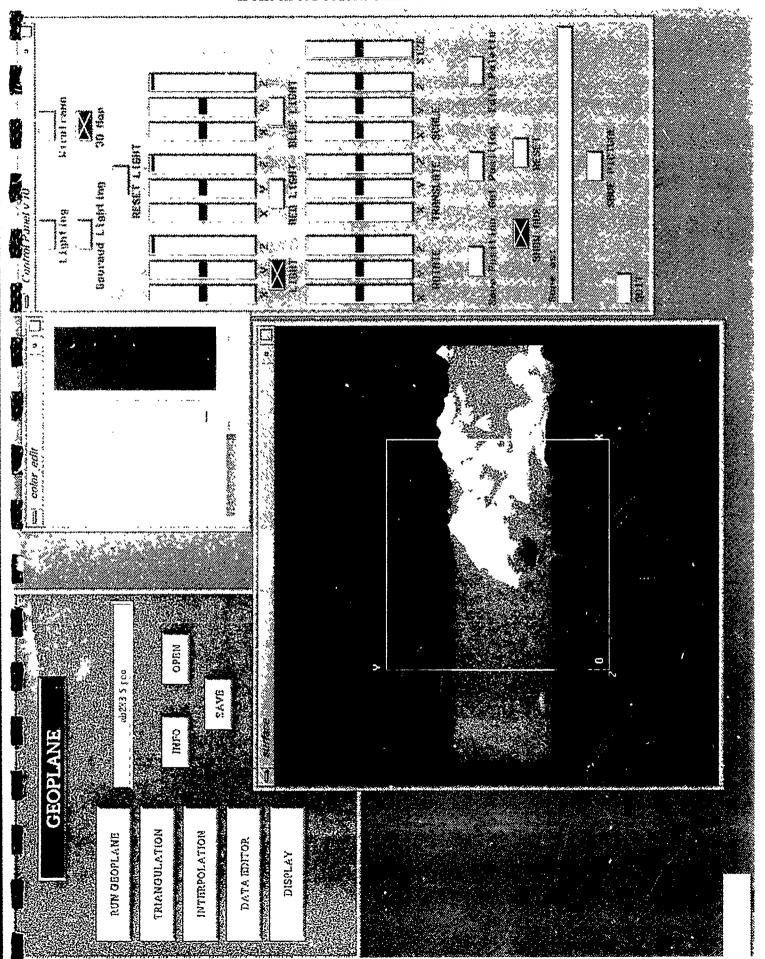

Last, but not least, we describe some of the features associated with the menudriven graphics system of GEOFORM. In the GEOPLANE panel, we have a button in which the file name to be loaded is inserted. Then, triangulation takes place upon clicking on the triangulation button. After the determination of missing points takes place, the interpolation button gets clicked. Then the data editor is triggered and the display provides the surface. The button labeled 'option' allows either normalization, smoothing by killing peaks, or a logarithmic scale contraction.

Another panel, the control panel, allows changes of light intensities, changes of colors, changes of individual rotation angles, and allows saving of files under the button 'Save Picture'. The color editor selects the bit of the graphics involved and allows the insertion of shading under the control panel instructions. These panels, as well as their sub-panels provide complete graphics control of the surface to be displayed either as a wire mesh or as a shaded solid surface.

The remarkable flexibility of displaying results is best illustrated in the hydrodynamic pictures provided below. In Figures 12-15, we apply GEOFORM to the visualization of Came fronts in turbulent flows. In Figures 16-20, we apply GEOFORM to the visualization of random of multi-frequency Rayleigh-Taylor instabilities occurring at density interfaces.

In conclusion, we have developed new algorithms for data preprocessing and organization, triangulation and interpolation. Numerous tests verify the efficiency and numerical stability of these new algorithms. In particular, the surfaces are glued together from small elements, depending on a finite number of neighboring points, but smoothly connected to each other. A listing of the GEOFORM family of codes is given in the Appendix.
